I, the undersigned, being an officer duly authorised in accordance with Section 74(1) and (4) of the Deregulation & Contracting Out Act 1994, to sign and issue certificates on behalf of the Comptroller-General, hereby certify that annexed hereto is a true copy of the documents as originally filed in connection with the patent application identified therein.

In accordance with the Patents (Companies Re-registration) Rules 1982, if a company named in this certificate and any accompanying documents has re-registered under the Companies Act 1980 with the same name as that with which it was registered immediately before re-registration save for the substitution as, or inclusion as, the last part of the name of the words "public limited company" or their equivalents in Welsh, references to the name of the company in this certificate and any accompanying documents shall be treated as references to the name with which it is so re-registered.

In accordance with the rules, the words "public limited company" may be replaced by p.l.c., plc, P.L.C. or PLC.

Re-registration under the Companies Act does not constitute a new legal entity but merely subjects the company to certain additional company law rules.

Notes

Please type, or write in dark ink using CAPITAL letters. A prescribed fee is payable for a request for grant of a patent. For details, please contact the Patent Office (telephone 071-438 4700).

Rule 6 of the Patents Rules 1990 is the main rule governing the completion and filing of this form.

Do not give trading styles, for example, 'Trading as XYZ company', nationality or former names, for example, 'formerly (known as) ABC Ltd' as these are not required.

Warning

After an application for a Patent has been made, the Comptroller of the Patent Office will consider whether publication or communication of the invention should be prohibited or restricted under Section 22 of the Patents Act 1977 and will inform the applicant if such prohibition or restriction is necessary. Applicants resident in the United Kingdom are reminded that under Section 23, applications may not be filed abroad without written permission unless an application has been filed in the United Kingdom for a patent for the same invention and either no objection prohibiting publication or communication has been given, or such direction revoked.

IMPROVEMENTS IN AND RELATING TO APPARATUS
AND METHODS FOR MATERIALS INVESTIGATION

This invention is concerned with improvements in and relating to apparatus and methods for materials investigations. The invention is particularly, but not exclusively, concerned with investigating gamma ray emissions from materials. The invention is still more particularly, but not exclusively, concerned with correction techniques in such investigations and the provision of a new correction technique.

In a variety of situations it is necessary to investigate emissions from radioactive sources in or on materials to form a basis for a variety of subsequent decisions, actions or further considerations. The investigations of the samples may relate directly to the emission, for instance the emission source, or indirectly, for instance the consideration of associated non-emitters or emitters which are not directly measurable. The emissions of interest are in particular gamma ray emissions, but other emission forms may be considered additionally or alternatively.

Emission investigation is particularly important in waste evaluation cases. For a given waste sample it is desirable to be able to determine a variety of unknowns. The unknowns may include, but are not limited to, one or more of the level, type, constituents, nature and distribution of the emissions, emission sources, associated materials or associated factors.

When taking measurements of the radioactive waste contained in a sample using prior art techniques it is necessary to make a number of assumptions to gain a solvable system. One such assumption for certain correction techniques is that the materials are homogeneously distributed within a body or container and, in particular

-2-

that the density profile of the material within the container is even. Given the various materials encountered and the varying size and shape of the materials potentially making up the waste this is not a truly valid assumption. Further variations occur in practice as materials settle or move over time, for instance during transportation.

Relevant correction techniques accept this assumption and are qualified by an error level as a result. For safeguard reasons the level of radioactive sources in a sample should be determined as accurately as possible. In safety cases the error requires that the level be placed at the worse case level. As a consequence the level of radioactive sources is frequently over estimated, with consequential complexity of further handling or storage, as well as cost penalties.

The present invention seeks, amongst other aims, to provide a technique in which greater account of variations or potential variations in density are taken. The improved account may be used in accounting for the effects of the material on the emissions as detected.

According to a first aspect of the invention we provide a method of investigating radioactive sources in a body of material provided at an investigation location, the body of material comprising a plurality of samples, the method comprising detecting a portion of the emissions arising from a sample, the detected portion relating to a detected level, the detected level being corrected according to a correction method to give a corrected level, the method being repeated for one or more of the other samples, the correction method for one or more of the samples comprising providing a generator of radioactive emissions and detecting the radioactive emissions from the generator with the sample at the investigating location, the relationship of the emissions detected with the sample at the investigating location to the

-3-

emissions which would be detected with the sample absent from the investigating location determining a characteristic of the sample, the determined characteristic being employed as a factor in the correction method used for that sample to obtain the corrected level.

The body of material may be free standing, but is preferably contained in a container. The sample may include the part of the container associated with that part of the body of material.

Preferably the sample is a portion of the body of material which extends from one side of the body through to the other. The sample may be a segment or slice through a body of material, preferably a segment or slice which extends outwards to the limits of the body of material in two dimensions. Preferably the sample is taken horizontally through the body of material. Preferably the sample has substantially the same thickness throughout the body of material. Preferably the thickness of the sample is its depth.

The samples may be investigated in order, for instance from one end of the body of material to the other.

Preferably the generator of emissions is a radioactive source provided externally of the position occupied by the container and/or body of material in use. Preferably the generator is provided in opposition to the detectors therefore.

The relationship of the emissions detected with the sample at the investigating location to the emissions which would be detected with the sample absent the investigating location may be the ratio of the respective count rates for the detectors. Preferably the emissions leaving the generator count rate is determined in the absence of the sample. The absence may be an absence of any body of material in the investigating location. The relationship may

-4-

be based on the ratio R/R_0 , where R is the rate at which the emissions are detected with the sample in place and R_0 is the rate of emissions which would be detected without the sample in place. Preferably the relationship is based on, and ideally equates to $-\ln(R/R_0)$.

Preferably the characteristic determined is a function of the density of the sample and preferably the density of the sample. The characteristic may be a function of the effective amount of material in the sample. The characteristic may relate to the effective amount of material determined to be in a sample relative to one or more other samples.

The determination of the characteristic for one or more or all of the samples may be based on the interrelationship of a plurality of potential variables. Preferably the variables include one or more of, and most preferably all of :-

i) the relationship of the emissions which would be detected without the sample present to the emissions detected with the sample in place, more preferably the relationship of R and R_0 , where R is the rate at which the emissions are detected with the sample in place and R_0 is the rate of emissions which would be detected without the sample in place;

ii) the attenuation effects of the sample, more preferably μ , where μ is the mass attenuation coefficient;

iii) the path of the emissions through the sample, more particularly, x , where x is the thickness of the sample (between source and detector);

iv) the density of the sample, ρ .

Preferably the determination of the characteristic is based on the equation :-

$$R = R_0 \exp(-\mu\rho x)$$

-5-

where the symbols have the meanings referred to above.

Preferably under the conditions of the investigation x and/or μ , and most preferably both are substantially constant. Preferably x is kept constant by fixed relative generator, detector and sample positions (the sample may rotate without affecting this). Preferably μ is substantially constant due to the energy of the generator emissions. An energy of greater than 400keV, preferably greater than 1000 keV and ideally greater than 1300 keV may be used. Preferably the source is as detailed in the British Nuclear Fuels PLC UK Patent Application filed 11 January 1999 and referenced P17454, the contents of which are incorporated by reference.

Preferably the amount of material in a sample is a function of the effect on transmission of generator emissions by that sample, the total amount of material being proportional to the effects of all the samples, the fraction of the total material in a particular sample being a function, preferably a ratio, of that sample's effect on transmission to the sum of all the effects. The effect on transmission of a sample may be given a numerical value, the amount of material in that sample, and/or its mass, being defined as the numerical value for that sample divided by the sum of the numerical values for all the samples, multiplied by the total mass. A density value for each sample may be made in this way by virtue of the known volume of the sample.

Preferably the amount of material in a sample, V_s , is made proportional to the ratio of R to R_0 , and more preferably is based on, and ideally equates to $:- -\ln(R/R_0)$. In this way the total amount of material in the body of material is proportional to the sum of each sample amount, $\sum V_s$. Preferably the fraction of the body of material in a given sample is $V_s/\sum V_s$.

-6-

Preferably the characteristic is determined based on a number of variables including one or more of, and ideally all of, :-

- I) the total mass of the body of material, M;
- ii) the total volume of the body of material, V;
- iii) the total number of samples forming the body of material, N;
- iv) the amount of material in a given sample, Vs;
- v) the sum of all the values proportional to the amounts of material in the sample volumes, $\sum Vs$;
- vi) the density of the sample.

Preferably the characteristic is determined based on the equation :-

$$\rho = (N.M/V) \cdot (Vs/\sum Vs)$$

Preferably the characteristic, and particularly the density is used in correcting the detected level to the corrected level, for instance by established subsequent techniques, such as those set out in the Los Alamos primer, 2nd Edition, March 1991, ISBN0-16-032724-5.

According to a second aspect of the invention we provide apparatus for investigating radioactive sources in a body of material, the body of material comprising a plurality of samples, the apparatus comprising :

one or more detectors for emissions from the sources, the detectors generating signals indicative of the emissions detected;

an investigating location into which the sample is introduced;

signal processing means for relating the detector signals to a detected level for the sources;

-7-

processing means providing a correction method for correcting the detected level for the sources to give a corrected level;

the apparatus further comprising :

a generator of radioactive emissions, at least of portion of the emissions entering the investigating location and, in use the sample;

one or more detectors for detecting the generator emissions with the sample at the investigating location;

processing means for determining a characteristic of the sample based on the relationship of emissions detected with the sample at the investigating location to emissions which would be detected with the sample absent, the characteristic being employed by the processing means as a factor in the correction method used for that sample to obtain the corrected level.

The source emission detectors and the generator emission detectors may be the same in one or more or all cases.

The signal processing means and/or processing means for the correction method and/or processing means for the determined characteristic may be one and the same.

The second aspect of the invention may include any of the features, options and possibilities set out on the first aspect of the invention, including apparatus suitable for the implementation of the method steps detailed therein.

The first and/or second aspects of the invention may further include any of the features, options, possibilities and steps set out below.

The sources may be singular or plural in disposition and/or type. The sources may be one or more isotopes of one

-8-

or more elements. The sources may be alpha and/or beta and/or gamma emitters, but are preferably gamma emitters at least.

One or more sources of the same type and/or of different types may be present in the sample. The sources may be homogeneously distributed, or more usually, unevenly distributed. The size and/or shape and/or mass of a source may be different from the size and/or shape and/or mass of another source in the sample, be they of the same or different types.

The sources may be investigated by detecting one or more of their emitting energies. Thus a characteristic energy of an isotope may be detected.

The sources may be investigated directly, for instance they contribute directly to the detected level, and/or the sources may be investigated indirectly, for instance they do not contribute directly to the detected level but are associated with sources which do.

The samples may be gaseous and/or liquid and/or solid. The samples may contain one or more non-emitting or non-source materials. The materials may include one or more of metals, such as iron, steel, aluminum; wood; glass; plastics, such as Polythene, PVC; liquids, such as water.

The container preferably entirely encloses the body of material. The container may be of metal or of concrete or a combination of such materials. Drums are a particularly preferred container, such as right cylindrical drums.

The containers may be of one or more standard sizes. The height and/or diameter of the containers may be standard.

Preferably the containers introduced to the investigating location one at a time. The containers may be introduced by conveying along a surface, preferably a horizontal surface. The surface may include or be formed of a plurality of rollers. Preferably the container is removed

-9-

from the investigating location in a manner equivalent to its introduction.

The investigating location is preferably provided in proximity to the emission detector or detectors. The investigating location may be provided in proximity to one or more radioactive sources. The sources are preferably intended to transmit radiation through the sample. Ideally the investigating location is provided between the detector(s) and the transmission source(s).

The sample, preferably the container for it, may be rotated at the investigating location. Preferably the rotation presents different portions of the sample in proximity to the detector(s) and/or transmission source(s). the rotation may be continuous or stepped. The rotation may be provided at between 5 and 25 rpm.

Preferably the sample and/or body of material and/or container are weighed at the investigating location, for instance by the turntable used to rotate it.

The sample, preferably the container for it, may be raised and/or lowered at the investigating location. Preferably the raising and/or lowering presents different portions of the sample to the detector(s) and/or transmission source(s). the raising and/or lower may be continuous or stepped. Preferably investigations are performed as the sample is lower and raised.

The sample may be rotated and/or lower and/or raised.

A single detector may be used. Preferably a plurality of detectors, for instance three, may be used.

The detectors may be of the high purity germanium type.

Preferably the detectors are collimated to restrict their field of view to the body of material of which the sample is the whole or a portion thereof. Where the sample is less than the whole of the body of material, preferably the detectors are collimated to restrict their field of view to the sample only. The sample is preferably a slice or

-10-

segment of the whole. The segments may be of the same thickness.

Preferably the detected level is obtained from a passive counting stage. Preferably the transmission based investigations are performed before and/or after the passive count stage.

Preferably the transmission source(s) is provided in opposition to the detector(s). Preferably the same number of transmission sources are provided as there are detectors. It is particularly preferred that the transmission source be provided according to nature of the transmission source detailed in British Nuclear Fuels PLC UK Patent Application detailed reference P17454 filed on 11 January 1999.

One or more surface dosimeters may be provided. Preferably the surface dosimeters are configured to investigate gamma emitting sources. Alpha and /or beta emitting sources may alternatively or additionally be investigated.

Various embodiments of the invention will now be described, by way of example only, and with reference to the accompanying drawings in which :-

Figure 1 illustrates schematically an instrument suitable for implementing the present invention;

Figure 2 shows the density measurements obtained during scans of an instrument employing the technique of the present invention, on four constructed, nominally, homogeneous material; and

Figure 3 shows a density measurement obtained during a scan of an instrument employing the technique of the present invention, on a constructed non-homogeneous material.

The instrument illustrated in Figure 1 is suitable for investigating gamma emission sources in a variety of situations and materials. The system 1 is particularly

-11-

designed to investigate waste samples presented in drums 3 to investigating location 5.

The drums considered may be in a variety of sizes, but the instrument is readily adapted to consider 100, 200 and 500 litre drums. Masses of waste, such as 40kg to 550kg, can readily be accommodated.

The drums 3 may be provided with a barcode which can be examined by a barcode reader on the system 1 so as to permanently assign results obtained to that drum 3.

The system 1 features a conveying table 7 formed of a large number of parallel rollers 9, onto which the drums are lowered. Cranes, forklift trucks and other lifting and manoeuvring means can be used to this end.

The conveying table 7 leads to the investigating location 5 and then onward out the other side to a dismounting location 11 from which the drums 3 are lifted. This set up allows the flow of samples for investigation through the system.

The drum 3 is supported at the investigating location 5 by a turntable 13 which again is formed by a number of parallel rollers 15 mounted on a moveable frame 17. The frame 17 can be rotated about a vertical axis, using a motor (not shown), so as to rotate the drum 3 about its longitudinal axis at the investigating location 5. A rotational rate of 12 rpm is preferred, but stepped rotation can be used. The frame 17 can also be provided with the option of being raised and lowered relative to the level of the surrounding conveying table 7, using electrical drives, hydraulics or other systems (not shown), so as to adjust the vertical positioning of the drum 3 within the investigating location 5. The lowering and rotating motions may be applied simultaneously.

The turntable 13 and frame 17 are configured to weigh the drum 3 whilst it is on the turntable 13.

-12-

On either side of the investigating location 5 are investigating assemblies 19, 21. In general one of these assemblies 19 acts as the, optional, transmission side and the other 21 as the detecting/receiving side for the investigations.

The detecting/receiving side 21 provides one or more detectors 23 for the emission type under consideration. The detectors 23 are collimated using shields 25 to give a restricted field of view into the investigating location 5 for each detector 23. Through the use of variable aperture collimators (not shown) the range of radioactivity level for the waste which can successfully be handled is increased. The field of view is generally configured to be a slice through that investigating location 5, the slice being substantially parallel to the turntable 13 and/or perpendicular to the axis of the drum 3 under consideration.

For gamma rays the detectors may be of the germanium type, for instance high purity germanium detectors. LRGS or HRGS detectors may be used, with electrical or LN₂ cooling for HRGS detectors.

The provision of more than one detector, collimated to different fields of view, allows a greater number of measurements to be taken simultaneously, hence increasing the throughput for the system.

The detectors 23 monitor gamma rays originating in their field of view in the drum 3 and in effect generate count rates. A count time of less than 30 minutes is generally employed.

The signals obtained from the detectors are fed to processing electronics 27 and hence to a CPU 29 and operator display 31. Operator control and inputs are facilitated through keyboard 33.

The processing electronics 27 are provided with error handling functions and diagnostic facilities, as well as providing the appropriate calibration functions.

-13-

Processing of the signals gives detailed information on the assay of waste material in the drum 3, the isotopic make-up of the waste. More details of these analyses are discussed below. The results can be used to classify waste according to the relevant disposal categories, including those below a deminimus level which can be characterized as non-radioactive. The results can be expressed the identification of fission products, activation products or MGA code. The realties can also be combined with the "fingerprinting" technique to give non-measurable isotope determinations.

The results obtained can be improved using a variety of potential correction techniques. Correction based on weight and/or differential peak adsorption and/or use of a transmission source may be used. In this invention the new correction techniques detailed in the same applicant's UK Patent Applications designated P17454 and/or P17600 also filed on 11 January 1999 may also be used and details of those techniques are fully incorporated herein by reference. The manner in which the correction techniques are employed may be as provided in British Nuclear Fuels PLC UK Patent Application referenced P17455 filed 11 January 1999, the contents of which are incorporated by reference.

Through the use of a transmission source or sources 35 on transmission side 19 in combination with stepped rotation of the drum 3 tomographic style investigations of the drum can be made to give plots of density distribution and radioactive distribution for the drum 3.

Surface originating alpha and/or beta emissions, and most preferably gamma emissions, for the drum 3 can also be measured using optional dosimeters 37. The dosimeters are normally provided on the transmission side 19 in proximity with the surface of the drum 3.

-14-

As discussed above three different known correction techniques may be deployed. The principles and operation behind each of these is now discussed.

Weight based correction seeks to account for the attenuating effects of the body of material the sources are in by a factor based on the body of materials density. The total mass of the entire body of material is divided by the total volume of the body of material, more commonly the total volume of the container for the body, to give an overall density value for the entire body/container. This single value is then used in the correction of the detected count to account for the reduction arising due to attenuation.

Differential peak absorption based correction again seeks to account for the attenuation effects of the material, but through a more direct investigation of attenuation. The gamma emissions from a source anticipated to be in the body of material at two characteristic energies are considered. The ratio of the emissions at one energy to the emissions at the other energy is known (1:1, for instance, for Co-60) without attenuating materials, and this base ratio is compared with the actual ratio measured with the attenuating effects of the body of material present to give a factor relating to the attenuating effect and hence allowing correction.

Transmission source based correction comes in a variety of forms, but each is generally based on determining attenuation effects on emissions from within the body of material by measuring the attenuation on externally sourced gamma emissions. Emissions at a known energy from the transmission source are detected after their passage through the body. The ratio of the detected emissions with the body of material present is compared with the detected emissions which would occur without the material. The attenuation is corrected for based on this difference. The energy of the

-15-

transmission source is selected to be close to the energy of the emissions from the sample which need correcting.

Whilst the above mentioned correction techniques are all useful in addressing a number of areas of potential error or variation in the results, a number of assumptions are still applied in reaching the calculated results from the measured information.

One of the particular areas of concern is the assumption that the density profile of the material in a container or drum under consideration is even. That is to say the density of the top portion of the drum is the same as the middle of the drum and is the same as the bottom of the drum.

Clearly the material, such as waste, introduced into a container will in many cases not be the same throughout the filling process. Even within the same general type of material variation occurs, for instance the size of the pieces and hence how they fit together within the drum. In many case different materials will be introduced at different times as the drum fills, potentially with those materials having different densities from one another. Additionally the materials may have different properties, for instance fluids will tend to flow downward and occupy the lower part of a drum fully, whilst potentially leaving voids in the upper part of the drum. Still further problems occur in the case of only partially filled drums where a substantial void exists at the top of the drum as a result.

As a wide variety of variations in the density profile are likely to be encountered in practice, the prior art technique of weighing the drum and dividing that mass by the volume of the standard drum size in question, to give a single density value averaged for the whole drum is clearly a source of potential error in all cases and actual error in almost all cases.

-16-

The correction technique of the present invention aims to combine weight measurements for the drum with transmission based measurements for the drum in a meaningful manner to address the issue of accurate correction.

The technique is based on considering the contents of the drum as a number of distinct parts, for instance horizontal segments through the drum, each of the segments being treated separately from the others in terms of its density value. By treating the drum as a number of potentially different density parts the errors referred to above are substantially removed. This division of the drum into segments and allocation of a density value to each segment cannot be made based on the weight of the drum alone.

To achieve the aim the technique evaluates the amount of material in a given segment by means of transmission source based investigations.

If R_0 is the rate at which photons from an external source are detected in the absence of the drum and R is the rate of detection of those photons with the drum present then :-

$$R = R_0 \exp (-\mu \rho x)$$

where μ is the mass attenuation coefficient, ρ is the density of the sample and x is the thickness of the matrix.

For any given drum x will be constant as this is the path length through the drum (56cm for a 200 litre drum, for instance). At high gamma energies, say greater than 400keV, μ can be treated as effectively constant too. Experimental demonstration of this is provided below. In effect these valid assumptions make ρ proportional to $-\ln(R/R_0)$.

For a given segment or slice, s , through the drum, the amount of material in that slice, V_s , is assigned the value $-\ln(R/R_0)$. The total amount of the material present in the

-17-

drum is thus defined as proportional to $\sum V_s$; the sum being for all the slices of the drum.

Following this definition, the fraction of the whole body of material in a given slice, s_1 , is given by $V_{s1}/\sum V_s$. As the total mass of the drum is known (from weighing), as the total volume of the drum is known (from measurement or as a standard size) and as the number of segments into which the drum has been divided is known (from the analysis control), then the density is defined as :-

$$\rho = (N.M/V) . (V_s/\sum V_s)$$

The provision of more accurate density information specific to each slice allows more accurate attenuation correction for that slice and hence greater overall accuracy.

The above mentioned technique was tested experimentally in two separate sets of experiments.

In the first set a series of homogeneous drums were scanned in position on the turntable of the type of instrument described above in relation to Figure 1. The scan was performed in 12 segments, in each case the drum was presented on a carrying puck which in effect equated to the 11 segment, with the 12 segment equating to the turntable itself and with the first segment being above the top of the drum.

The results from this set of tests for a concrete, a hulls, a PVC and a paper carrying drum are set out in Figure 2.

The results clearly show the change in density determined before the drum is reached, segment 1, as the puck is reached, segment 10 and the turntable, segment 11.

More importantly the measurements reveal that the PVC drum is not as homogeneous as thought.

-18-

Table 1 summarizes the density measurements derived from an assumption of homogeneous material and those calculated by the transmission/weight correction based technique. Good agreement for all the densities of material was achieved.

TABLE 1

MATRIX	KNOWN DENSITY	TRANS/WEIGHT DENSITY
Paper	0.066 +/- 0.004	0.054 +/- 0.008
PVC	0.45 +/- 0.02	0.46 +/- 0.05
Hulls	1.47 +/- 0.07	1.49 +/- 0.04
Concrete	2.10 +/- 0.10	2.12 +/- 0.08

The ability of the technique to pick up the variations in density is still more apparent from the second set of tests. The results of these test are illustrated in Figure 3 with regard to a deliberately non-homogeneous drum. The drum was constructed, working up, from rubble (most dense), from paper and PVC (least dense) and was topped off with bottles of water (intermediate density).

The figure clearly illustrates that the technique picks out each of these densities in turn.

The more accurate density measurements can be used to correct the processing of the results of the detectors to give a better resolution of the level of radioactive material within the waste. The density measurements could additionally or alternatively be used in the other correction techniques to improve them too.

When under taking a transmission/weight based correction of this type the selection of an appropriate transmission source is important. A transmission source of the type described in the British Nuclear Fuels UK Patent Application filed on the same date as this initial application, under reference no. P17454, is particularly

-19-

suitable and the contents of that application are incorporated herein in that regard.

In general the source should be selected to have a highly penetrating gamma energy (for instance, in the range 1000 to 2000keV) and preferably be of high branching fraction. Use of such energy level sources ensures that the assumption that μ is constant remains a valid one. The lack of variation of μ between materials is clearly illustrated in Table 2, at an energy of approx. 1500keV.

TABLE 2

MATERIAL	μ (g.cm ⁻²)
Iron	5.02E-2
Lead	5.27E-2
Magnesium	5.29E-2
Sand	5.35E-2
PVC	5.49E-2
Water	5.94E-2
Polythene	6.11E-2
AVERAGE	5.50E-2

The penetrating power of the transmission source is also important as this is a limiting factor on the density range which can be accommodated by the present technique.

Table 3 sets out the fraction of photons which will penetrate a 56cm diameter drum, with $\mu=5.25E-2$ g.cm⁻², for a variety of material densities between 0 and 3.0g.cm⁻³. The count rate for the detector and associated precision for a 15 minute each way assay with 12 segments (i.e. 75 seconds per segment) is shown too.

DENSITY (g.cm ⁻³)	FRACTION TRANSMITTED	COUNT RATE	COUNTS IN 75 SEC.	1 SIGMA ERROR ON 75s COUNT (%)
0.0	1.0	893	67000	0.4

-20-

0.5	0.23	205	15400	0.8
1.0	0.053	47.3	3550	1.7
1.5	0.012	10.7	800	3.5
2.0	0.0028	2.50	188	7.3
2.5	0.00064	0.57	43	15
3.0	0.00015	0.13	10	32

Based on this approx. 1500keV source densities up to 2.5g.cm^{-3} (above the upper level of most samples encountered in practice) could be successfully addressed. Increased penetrating power and increased count times could raise the density level still further.

As demonstrated above the technique offers improved performance and accuracy of results, whilst being applicable to a wide variety of waste types, including partially filled drums and the hardest wastes normally encountered, those of high density.
